GREEN ET AL.

© Katie Carolan 2024

Why are (almost) all the protostellar outflows aligned in Serpens Main?
(Green et al., June 2024)

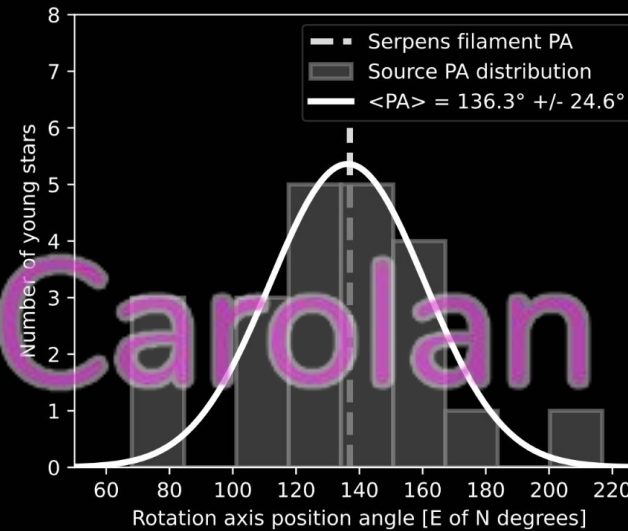

Figure 5. Distribution of measured average position angles for all 22 sources, clustering around the filament PA = 139°. The black curve is a Gaussian fit to the distribution with parameters (mean and standard deviation) given in the legend.

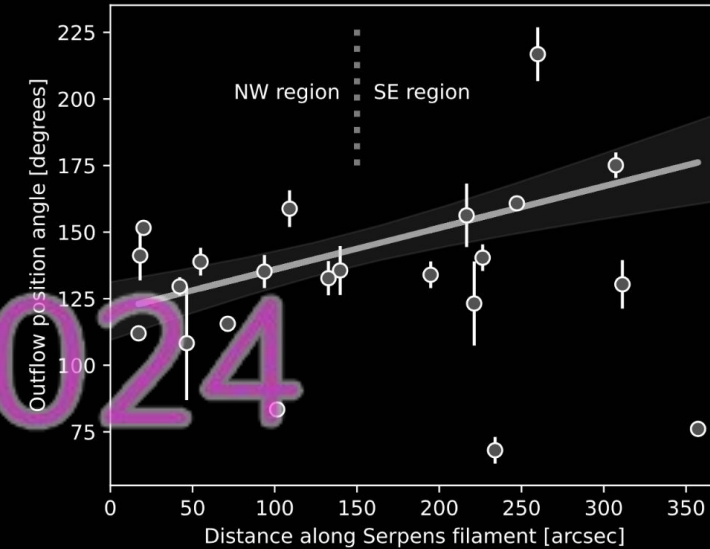

Figure 6. PA as a function of position along the filament. The PAs of the NW region are more correlated than the SW region. The line is the best linear fit after removing three outliers with the highest and lowest measured PA. The shaded region shows the 99% confidence level of the fit.

CONCLUSIONS ARE DRAWN

© Katie Carolan 2024

Why are (almost) all the
protostellar outflows aligned
in Serpens Main?
(Green et al., June 2024)

- NIRCcam/F480M is particularly well-suited to detect outflows because it contains molecular, atomic, and ionic tracers that all emit strongly in protostellar outflows/jets. The result is a mixed morphological catalog with a high detection rate.
- 12 outflows were identified in the northwestern filament/region, while 8 outflows were identified in the southeastern filament/region. Additionally, two prominent disk shadows were confirmed in the central region.
- The axes of the 12 outflows in the NW region are inconsistent with random orientations and align with the filament direction from NW to SE. Additionally, the position angle of jets/outflows from the 2 identified disk shadows align with the filament axis. We estimate $< 0.005\%$ probability of the the observed alignments if sampled from a uniform distribution in position angle.
- The position angles of the outflows align with SOFIA/HAWC+ 214 μm dust polarization vectors measured locally around each driving source. However, the disk shadows do not align with their local magnetic fields. This broad alignment does not apply in the SE region. Few of the 8 identified outflows in this region align with the filament axis, or with the dust polarization vector.
- The density of outflows detected in this catalog (~ 66 outflows per pc^2) is higher than other low mass star forming regions (e.g., NCC 1333), and ten times greater than observed by JWST/NIRCcam in Carina (NGC 3324).

ALIGNED OUTFLOWS in SERPENS

The image is a deep-field astronomical photograph of the Serpens Main star-forming region. It features a dense field of stars, many of which are surrounded by bright, multi-colored outflows (proplyd outflows) in shades of orange, red, and yellow. The background is a dark, star-filled space with some diffuse interstellar dust clouds. The overall scene is vibrant and dynamic, capturing the early stages of stellar evolution.
